# Temporal Objects for Spatio-Temporal Data Models and a Comparison of Their Representations* 

Martin Erwig \& Markus Schneider \& Ralf Hartmut Güting<br>FernUniversität Hagen, Praktische Informatik IV<br>D-58084 Hagen, Germany<br>[erwig, markus.schneider, gueting] @fernuni-hagen.de

#### Abstract

We present a new approach to temporal data modeling based on the very general notion of temporal object. Moreover, we propose the database embedding of temporal objects by means of the abstract data type (ADT) approach. We consider the expressiveness of different temporal database embeddings, and we discuss the combination of temporal and spatial objects into spatio-temporal objects in (relational) databases. We explain various alternatives for spatio-temporal data models and databases and compare their expressiveness.

## 1 Introduction

In the past, in spite of many similarities, research in spatial and temporal data models and databases has largely developed independently.

Spatial database research [Gü94] has focused on modeling, querying, and integrating geometric and topological information in databases. For the modeling of spatial objects spatial data types (e.g. [SV89, SH91, GS95, Sc97]) have been identified as appropriate and efficient abstractions for modeling the geometric structure of spatial phenomena as well as their relationships, properties, and operations. We base our definition of spatial objects on the point set approach and on point set topology [Ga64]. A spatial object is assumed to be represented by a generally infinite point set with certain properties from which different structures like the boundary or the interior can be identified. There are mainly two reasons for this way of modeling: spatial objects modeled by the point set approach are efficiently implementable and can be easily embedded in a (relational) database. This leads us to the specific subclass of linear spatial objects where linearity is given through polygonal approximations. Moreover, the vast majority of optimization methods and indexing techniques builds upon such linear representations. Besides, this approach fits very nicely with our model of temporal objects.

Temporal database research [ $\mathrm{TCG}^{+} 93$ ] has concentrated on modeling, querying, and recording the temporal evolution of facts under different notions of time (valid time, transaction time) and thus on extending the knowledge stored in databases about the current and past states of the real world. Traditionally, temporal data has been modeled by tuple- or attribute-timestamped relations. This is a restricted view essentially preventing the treatment of continuous change of temporal data. In contrast, a more general

[^0]view is offered by a (simplified) definition of a temporal object as a function mapping time to a certain codomain under some constraints, and this is the first contribution of our paper:

1. We present a very general model of temporal objects whose definition is based on the observation that anything that changes over time can be expressed as a function over time.

Currently, there are increasing integration efforts striving for a combination of space and time in "spatio-temporal data models and databases". We have already discussed evolving problems and have presented a first approach for a data model in [EGSV98]. A few other papers already exist that deal with the integrated modeling of space and time, for instance, [Wo94,YC93], but they do not address the embedding in databases.

This paper now views the topic from a rather fundamental perspective and additionally makes the following contribution:
2. We propose the database embedding of temporal objects in the spirit of the abstract data type approach applied to the integration of complex objects into databases [SRG83, St86].
In spatial database technology, for quite some time, spatial data types have been integrated as ADTs for attributes in relational schemas (e.g. [Gü88, SH91, Sc97]). ${ }^{1}$ So far, temporal databases have been essentially based on atomic standard data types extended by an explicitly or implicitly given type for time. Tuples are associated with time stamps; each tuple describes the validity and the features of a fact or object. We show that temporal databases based on the ADT approach are more powerful than current ones and that a simple extension compensates this difference for a particular class of temporal objects.
3. We demonstrate the broad spectrum of integration options for temporal and spatial objects into spatio-temporal objects in (relational) databases and compare their expressiveness.

The variety of temporal and spatial data models offers many different possibilities for combining temporal and spatial objects into spatio-temporal objects in (relational) databases. We discuss this design space and explain different alternatives for spatiotemporal data models and databases. One of our main conclusions here is:

## Spatio-temporal objects are special cases of temporal objects

We compare the expressiveness of the different temporal, spatial, and spatio-temporal data models. We focus on object representations and defer the treatment of operations and query languages to a subsequent paper. For spatio-temporal data models we establish a representation hierarchy. An interesting visualization of spatio-temporal objects for the linear case is a three-dimensional view in the form of $3 D$-polylines for moving points and in the form of polyhedra for moving regions [EGSV98], respectively. We

[^1]show that, surprisingly, the polyhedra model is not comparable to any model of our hierarchy.

The rest of the paper is structured as follows: Sections 2 and 3 define a model for spatial and temporal objects and describe a representation for their use in databases. We also consider expressiveness of the different temporal modeling alternatives. Section 4 deals with the design space obtained when combining spatial and temporal objects. Various spatio-temporal data models are explained, and a number of relationships between the different models are shown. Section 5 concludes the paper.

## 2 Spatial Objects and Spatial Databases

### 2.1 Spatial Objects

Space is assumed to be composed of infinitely many points; it corresponds to the twodimensional Euclidean space $\mathbb{R}^{2}$. Each spatial feature $S$ is regarded as an arbitrary, possibly infinite, point set $S \subseteq \mathbb{R}^{2}$. We here take an ADT approach and use spatial data types for points and regions as appropriate abstractions of spatial phenomena. Elements of spatial data types are called spatial objects. The set of all spatial objects is denoted by SO $=$ Point $\cup$ Region where Point and Region are the set of all point and region objects, respectively, and we also speak of the SO-model. Mathematical definitions of regions can be based on point set topology; to avoid application-specific anomalies we use regular closed sets and regularized set operations [Ti80, ES97]. For the implementation we need finite descriptions of point sets, and we employ linear approximations of spatial objects. The set of all linear spatial objects is denoted by $\overline{\mathrm{S} O}$. Out of several implementation alternatives, our selection is to approximate regions by a type Polygon consisting of sets of polygons possibly with polygonal holes. The Points remain unchanged.

### 2.2 Representation of Spatial Objects in Databases

A relation scheme $R$ is written as $R\left(A_{1}: D_{1}, \ldots, A_{n}: D_{n}\right)$ where the $A_{i}$ are the attributes of $R$. For a relation $r: R\left(A_{1}: D_{1}, \ldots, A_{n}: D_{n}\right)$ holds: $r \subseteq D_{1} \times D_{2} \times \ldots \times D_{n}$. Tuples are described in the form ( $A_{1}=x, A_{5}=b, \ldots$ ); only the values of interest are shown.

Principally, there are two methods of integrating spatial objects into relational databases. The first method is to embed spatial objects directly as ADTs, i.e., a single attribute value contains a complete spatial object: $R(S: \alpha, \ldots)$ for $\alpha \in G E O=\{$ Point, Region, Polygon $\}$. This applies to the SO and $\overline{\mathrm{S} O}$ model. The corresponding relational data models are called SO-REL and SO-REL; they denote the set of relations with at least one attribute of a (linear) spatial data type. For simplicity we assume that each such relation has exactly one spatial attribute. The second method leads us to S-REL which denotes the set of relations modeling spatial features only with atomic standard attribute types. A polygon is represented as a set of tuples each storing the coordinates of two points representing a segment of the boundary representation of a polygon [BS77, Ro87].

A more detailed description of the $\mathrm{SO} / \mathrm{SO}$-models and their representation in databases is given in the full paper [ESG97].

## 3 Temporal Objects and Temporal Databases

### 3.1 A Model of Temporal Objects

When defining a model for temporal objects one has to decide about a model of time. We choose - mainly for consistency with the spatial domains - time to be continuous, i.e., time $=\mathbb{R}$. Now anything that changes over time can be expressed as a function over time, i.e., the temporal version of objects of a type $\alpha$ is given by a function of type time $\rightarrow \alpha$, called a temporal function. The type of all (partial) temporal functions is simply:

$$
\phi(\alpha)=\text { time } \rightarrow \alpha
$$

We have to deal with representations that are computationally tractable. This means that for an arbitrary temporal function $f \in \phi(\alpha)$ we can determine the value of $f$ at any time of its domain. Thus, we restrict $\phi(\alpha)$ to computable functions. It is also important to be able to compute values of the inverse function, i.e., ask for the times at which a temporal object took a specific value. Further restrictions result from the need to integrate temporal objects into the relational model and from compatibility with the chosen model for spatial objects. Thus, we restrict the domain of $\phi$ to finite sets of time points and intervals. For any type $\alpha$ that has a total order < (and equality =) we define the type of non-empty (open and closed) intervals over $\alpha$ as follows:

```
\(\mathfrak{l}(\alpha)=\cup\{\{[x, y]] x, y],,[x, y[] x,, y[ \} \mid x, y \in \alpha\}-\{\varnothing\}\) where
\([x, y]=\{a \in \alpha \mid x \leq a \leq y\},] x, y]=\{a \in \alpha \mid x<a \leq y\},[x, y[=\{a \in \alpha \mid x \leq a<y\}\), etc.
```

This way we can encode continuous parts of $\phi$ 's domain by intervals, i.e., the domain of a temporal object is given by a finite set of pairwise disjoint intervals (any time point $t$ can well be represented by a degenerated interval $[t, t]=\{t\}$.) We can now define the type constructor for temporal objects as:

$$
\begin{array}{ll}
\tau(\alpha)=\mathfrak{v}(\text { time }) \rightarrow \phi(\alpha) \quad(=\mathfrak{v}(\text { time }) \rightarrow \text { time } \rightarrow \alpha) \\
\text { where } \forall \omega \in \tau(\alpha): & \text { (1) } \forall I, J \in \operatorname{dom}(\omega): I \cup J \notin \mathfrak{l}(\text { time }) \\
& \text { (2) } \forall I \in \operatorname{dom}(\omega): \operatorname{dom}(\omega(I))=I
\end{array}
$$

This means a temporal object $\omega$ is defined on a set of pairwise disjoint and non-adjacent intervals and associates with each interval of its domain a (partial) temporal function whose domain is just that interval. The set of all temporal objects is denoted by TO, and we also speak of the TO-model. There are at least two reasons for considering only linear temporal functions as a further restriction of temporal objects: (i) it is difficult to compute with general functions, and (ii) a linear temporal function has a straightforward representation, which is particularly important for the integration into relations: store the function values of the boundaries of intervals and use predefined interpretations for deriving function values for the interior of intervals.

In order to formalize the notion of linearity we consider argument types $\alpha$ that have a certain algebraic structure (we call these types linear smooth): there must be a nontrivial type $\Lambda(\alpha) \subseteq \alpha \rightarrow \alpha$ of functions on $\alpha$ for which two conditions hold: first, a scalar multiplication is defined, i.e., $\forall f \in \Lambda(\alpha), r \in \mathbb{R}: r \cdot f: \alpha \rightarrow \alpha$ is a well-defined function (with $1 \cdot f=f$ ). Second, the function $\Delta: \alpha \times \alpha \rightarrow \Lambda(\alpha)$ yields for two values $x, y \in \alpha \mathrm{a}$ function $\delta$ which captures the "difference" between $x$ and $y$; in particular, $\delta(x)=y$ must
hold. Then, by virtue of the scalar multiplication, values in the interior of an interval can be computed by $\delta$. For instance, for $\alpha=\mathbb{R}$ the usual linear transition from $x$ to $y$ is captured by $\Delta(x, y)=\lambda x^{\prime} \cdot x^{\prime}+(y-x)$ where scalar multiplication is defined as: $r \cdot\left(\lambda x^{\prime} \cdot x^{\prime}+(y-x)\right)$ $=\lambda x^{\prime} \cdot x^{\prime}+r \cdot(y-x)$. The reason why $\Delta$ is defined to return a function and not simply a difference value is that the linear interpretation for $\alpha \in$ GEO is given by affine mappings (see Section 4), and for these the functional view is much easier to handle than the value approach.

Now the linear temporal object ( $\overline{\mathrm{TO}}$ ) model can be defined as a linear specialization of the TO-model (very much like $\overline{\mathrm{SO}}$ is a specialization of SO ). By $\mathrm{I} t_{1}, t_{2} \mathrm{I}$ we denote an arbitrary open, closed, or semi-open time interval, and we let $\|t\|=\left(t-t_{1}\right) /\left(t_{2}-t_{1}\right)$. We say that a temporal function $f:$ time $\rightarrow \alpha$ is $k$-piecewise linear if:

$$
\begin{aligned}
& \exists k \in \mathbb{N}: \operatorname{dom}(f)=\cup_{1 \leq i \leq k} I_{i} \text { with } I_{i}=\mathrm{I} t_{1}, t_{2} I \wedge \forall 1 \leq i<j \leq k: I_{i} \cap I_{j}=\varnothing \\
& \wedge \forall I_{i}:\left|I_{i}\right|>1 \wedge \forall t \in I_{i}: f(t)=(\| t \mid \cdot \Delta(x, y))(x) \\
& \text { where } x=\lim _{n \rightarrow \infty} f\left(t_{1}+1 / n\right) \text { and } y=\lim _{n \rightarrow \infty} f\left(t_{2}-1 / n\right)
\end{aligned}
$$

A $k$-piecewise linear function is always also $(k+1)$-piecewise linear. To get a canonical (and efficient) representation we look for minimal decompositions of intervals. Therefore, we say that $f$ is minimally decomposed (or maximally piecewise, or just $k$-piecewise) if $f$ is $k$-piecewise linear, but not ( $k-1$ )-piecewise linear. Then the minimal decomposition of $f$ is defined as the partition $\pi(f)=\left\{\left(I_{i},\left.f\right|_{I_{i}}\right) \mid 1 \leq i \leq k\right\}$ where $\left.f\right|_{D}=\{(x, f(x)) \mid x$ $\in D\}$. Now the type of linear temporal objects is defined by the type constructor $\bar{\tau}$ as follows.

$$
\bar{\tau}(\alpha)=\{\omega \in \tau(\alpha) \mid(1) \alpha \text { is linear smooth }
$$

(2) $\forall I \in \operatorname{dom}(\omega):|I|=1 \vee \omega(I)$ is $k$-piecewise $\}$

Note that we cannot simply restrict $\omega$ to be linear on each of its intervals, we rather have to refine this condition to finite partitions of each interval $I$ because $\omega$ might have different linear behaviors on $I$. Therefore, we have used the notion of piecewise linearity. It is obvious that linear temporal objects are a strict subset of (general) temporal objects:

Lemma 3.1. $\overline{\mathrm{T} O} \subset \mathrm{TO}$.

### 3.2 Representation of Temporal Objects in Databases

The integration of temporal objects into relational databases can be done principally in two ways: temporal objects can be embedded directly as ADTs, i.e., a single attribute contains a complete temporal object: $R(O: \tau(\alpha), \ldots)$. This applies to the TO and $\overline{\mathrm{T}}$ models. The corresponding data models are called TO-REL and TO-REL, and the y denote the set of relations with at least one attribute being of a (linear) temporal object type. For simplicity we assume in the sequel that each such relation has exactly one temporal attribute. ${ }^{2}$ In contrast, T-REL denotes relations with only atomic attribute types (including time). T-REL as defined below gives a unifying view on different traditional tuple-timestamped ${ }^{3}$ models of temporal databases. Each temporal object is represented
2. The general case requires that the time domains of different temporal objects have to be "synchronized" by finding a common interval refinement when mapping to T-REL. This is not difficult, but makes the definitions longer.
by a set of tuples each storing a value of type $\alpha$, a time stamp, and a flag $B$ indicating the future value behavior: $R(A: \alpha, T:$ time, $B:\{d, c, l\}, \ldots) . B$ specifies the values in between two time stamps, i.e, given two tuples ( $A=x, T=t_{1}, B=b, \ldots$ ) and $\left(A=y, T=t_{2}, \ldots\right)$ of a relation $r \in \mathrm{~T}-\mathrm{REL}$ where $\forall\left(T=t_{3}, \ldots\right) \in r: t_{3}<t_{1} \vee t_{3}>t_{2}$, the value of $A$ at any time $t_{1}<t<t_{2}$, denoted by $A(t)$, is:

| Interpretation | Definition | $b$ | Name |
| :--- | :--- | :---: | :--- |
| completely undefined | $A^{d}(t)=\perp$ | $d$ | discrete |
| valid up to the next definition | $A^{c}(t)=x$ | $c$ | (stepwise) constant |
| changes continuously | $A^{l}(t)=(\\|t\\| \cdot \Delta(x, y))(x)$ | $l$ | linear |

(In the informal model of [YC93] spline interpolation is suggested as another interpretation.) To be compatible with TO and $\overline{\mathrm{T}} \mathrm{O}$ we consider a further fl ag $C$ : BB for distinguishing closed and open intervals: $C=$ true $\Leftrightarrow A$ is a valid value at $T$ (otherwise, $A$ is used only for deriving values in the interior of the preceeding and/or the following interval).

In order to compare T-REL with TO-REL and $\bar{T} O-R E L$ we define the temporal object represented by a relation from T-REL. Let $r=\left\{\left(A=a_{1}, T=t_{1}, B=b_{1}, C=c_{1}, \ldots\right)\right.$, $\left.\ldots,\left(A=a_{n}, T=t_{n}, B=b_{n}, C=c_{n}, \ldots\right)\right\}: R(A: \alpha, T:$ time $, B:\{d, c, l\}, C: \mathbb{B}, \ldots) \in \mathrm{T}-$ REL be a (sub-) relation containing only tuples describing one temporal object (i.e., the projection to all attributes $\notin\{A, T, B, C\}$ yields a relation of a single tuple). First, we derive the set of temporal functions for the intervals represented in $r$ :

$$
\Phi(r)=\left\{\left\{\left(t, A^{b_{i}}(t)\right) \mid t_{i}<t<t_{i+1}\right\} \cup\left\{\left(t_{j}, a_{j}\right) \mid c_{j}=\text { true }, j \in\{i, i+1\}\right\} \mid 1 \leq i<n\right\}
$$

Next we have to map each interval to its corresponding temporal function. We get: $\{(\operatorname{dom}(f), f) \mid f \in \Phi(r)\}$. Note that this is not yet the final temporal object, since there are, in general, more intervals in the T-REL representation than in the corresponding temporal object. Therefore, we have to normalize by merging temporal functions on adjacent intervals. This can be done by the function $\gamma$ :

$$
\gamma(\omega)= \begin{cases}\gamma\left(\{(I \cup J, f \cup g)\} \cup \omega^{\prime}\right) & \text { if } \exists \omega^{\prime}: \omega=\{(I, f),(J, g)\} \cup \omega^{\prime} \text { with } I \cup J \in \mathfrak{l}(\text { time }) \\ \omega & \text { otherwise }\end{cases}
$$

Hence, the temporal object denoted by relation $r$ is finally given by:

$$
\sigma_{T}(r)=\gamma(\{(\operatorname{dom}(f), f) \mid f \in \Phi(r)\})
$$

For relations $r$ that do not properly represent temporal objects $\sigma_{T}(r)$ is undefined, i.e., $\sigma_{T}(r)=\perp$.

Next we have to define the representation of a linear temporal object $\omega$ as a relation $r \in$ T-REL. Therefore, we first partition each interval of $\omega$ 's domain into maximal subintervals so that the corresponding temporal function is linear on each of these subintervals. We obtain this through the minimal decomposition $\pi$. Note carefully, that we cannot represent "linear functions followed by a jump", but only jumps after stepwise
3. In contrast, attribute-timestamped models like that of [SS93] correspond more closely to the ADT view.
constant parts because we have spent for each interval only one attribute of type $\alpha$. This means that we cannot represent a function that evolves linearly from $x$ to $y$ and continues with $z \neq y$. Thus, the representation function $\rho$ described in the sequel is only partially defined.

Consider a $k$-piecewise temporal function $f$. Let $\operatorname{dom}(f)=\cup_{1 \leq i \leq k} I_{i}$ with $I_{i}$ $=\mathrm{I} t_{i, 1}, t_{i, 2} \mathrm{I}, x_{i}=\lim _{n \rightarrow \infty} f\left(t_{i, 1}+1 / n\right)$, and $y_{i}=\lim _{n \rightarrow \infty} f\left(t_{i, 2}-1 / n\right)$. If $x_{i}=y_{i}$, let $b_{i}=c$. Otherwise, if $y_{i}=x_{i+1}$, then $b_{i}=l$. Otherwise, $\rho$ " $(f)$ (see below) is undefined. Then

$$
\rho "(f)=\left\{\left(A=x_{i}, T=t_{i, 1}, B=b_{i}, C=\left(t_{i, 1} \in I_{i}\right)\right) \mid 1 \leq i \leq k\right\} \cup\left\{\left(A=y_{k}, T=t_{k, 2}, B=d, C=\left(t_{k, 2} \in I_{k}\right)\right)\right\}
$$

Now the relation representing any temporal function of a temporal object is given by:

$$
\rho^{\prime}(f)= \begin{cases}\{(A=f(t), T=t, B=d, C=t r u e)\} & \text { if } \operatorname{dom}(f)=\{t\} \\ \rho^{\prime \prime}(f) & \text { otherwise }\end{cases}
$$

Finally, the relation representing a complete linear temporal object is:

$$
\rho_{T}(\omega)=\cup_{(I, f) \in \omega} \rho^{\prime}(f)
$$

### 3.3 Expressiveness of Temporal Data Models

To compare the different models we use operations from the $\mathrm{NF}^{2}$ relational model [SS86] to describe mapping bewteen them. Let $v[A S: A ; f]$ be the nest operator that takes in addition to the set of attributes $A S$ to be nested a function $f$ that is applied to each resulting sub-relation $r^{\prime}$. Then $f\left(r^{\prime}\right)$ is stored under the attribute $A$ (instead of $r^{\prime}$ ). Similarly, the unnest operator $\mu[A: A S ; f](r)$ applies the function $f$ to the value of attribute $A$ of each of $r$ 's tuples and produces a relation of schema $A S$ that is embedded into $r$.

Next we can compare the different temporal data models. First, we show that $\overline{\mathrm{T}} \mathrm{O}-$ REL is more expressive than T-REL, but with two simple extensions T-REL becomes equivalent to TO-REL. This means that the ADT approach is essentially equi valent to simple temporal relational models as far as linear temporal behavior is concerned. We also show that, in general however, TO-REL is more powerful than both TO-REL and T-REL.

The difference between $\bar{T} O-R E L$ and T-REL lies essentially in the fact that one tuple in TO-REL is represented by a set of tuples (= sub-relation) in T-REL. We can define two simple transformations to map between TO-REL and T-REL. Any relation $r$ : $R(A: \alpha, T:$ time, $B:\{d, c, l\}, C: \mathrm{B}, \ldots) \in \mathrm{T}$-REL can be transformed into an equivalent relation $s \in \overline{\mathrm{~T}} \mathrm{O}-$ REL simply by

$$
s=v\left[\{A, T, B, C\}: O ; \sigma_{T}\right](r)
$$

Likewise, any relation $s \in \overline{\mathrm{~T}}$-REL can be transformed into a T-REL relation $r$ by:

$$
r=\mu\left[O:\{A, T, B, C\} ; \rho_{T}\right](s)
$$

Let $\mathrm{v}_{T}(\mathrm{~T}-\mathrm{REL})=\left\{v\left[\{A, T, B, C\}: O ; \sigma_{T}\right](r) \mid r \in \mathrm{~T}-\mathrm{REL}\right\}-\{\perp\}$, and let $\mu_{T}(\mathrm{~T}-\mathrm{REL})=$ $\left\{\mu\left[O:\{A, T, B, C\} ; \rho_{T}\right](r) \mid r \in \bar{T} O-R E L\right\}$. Now we first have:
Theorem 3.1. $v_{T}(\mathrm{~T}-\mathrm{REL}) \subset \overline{\mathrm{T}} \mathrm{O}$-REL.

Proof. Since $\sigma_{T}$ is a total function, it is clear that each T-REL can be transformed into a corresponding $\bar{T} O-R E L$. The fact that the inclusion is proper is grounded in the par tiality of $\rho_{T}$ : since each linear function followed by a jump cannot be represented by a T-REL, there are more TO-RELs than T-RELs.

There is an even more important difference between T-REL and TO-REL that gets lost by lifting T-REL to the ADT-level of $\bar{T} O-R E L$ : non-temporal attributes in a $\bar{T} O-R E L$ exist independently from the domain of the temporal attribute. In contrast, an additional (implicit) rule would be needed to distinguish temporal attributes from non-temporal ones in T-REL. This reflects the fact that attribute-timestamped temporal models are, in general, more expressive than tuple-timestamped models.

If we extend T-REL by storing an additional $\alpha$-attribute (and a second $C$-flag specifying the definedness at the end of intervals), we can actually represent all linear temporal objects in flat relations. Let us call such a model $\mathrm{T}^{+}$-REL. (Of course, we have to redefine and extend the $\rho_{T}$ and $\sigma_{T}$ transformations, too.) Then:
Theorem 3.2. $v_{T}\left(\mathrm{~T}^{+}\right.$-REL $)=\overline{\mathrm{T}} \mathrm{O}-\mathrm{REL}$ and $\mu_{T}(\overline{\mathrm{~T}} \mathrm{O}-\mathrm{REL})=\mathrm{T}^{+}$-REL.
Still the ADT-approach is more general when we do not restrict ourselves to linear behaviors. As a direct corollary of Lemma 3.1 we obtain:

Theorem 3.3. $\bar{T} O-R E L \subset$ TO-REL.

## 4 Spatio-Temporal Data Types and Data Models

Now that we know how to model spatial and temporal objects and how to integrate them into databases we can consider their combination.

### 4.1 Landscape of Spatio-Temporal Data Models

A straightforward approach is indicated by the fact that $\tau$ is a type constructor: it is obvious to apply $\tau$ to types from GEO to immediately obtain spatio-temporal objects (STO). The types of this model comprise moving objects, i.e., $\mathrm{MOV}=\{\tau($ Point $), \tau($ Region $)$, $\tau($ Polygon $)\}$ ). Again we can restrict ourselves to linear objects, both for the temporal and the spatial component, and obtain the following models and types:

| Model | linear component | Types |
| :---: | :---: | :---: |
| STO | - | $\tau($ Point $), \tau($ Region $)$ |
| $\overline{\text { STO }}$ | spatial | $\tau($ Point $), \tau($ Polygon $)$ |
| STO | temporal | $\bar{\tau}($ Point $), \bar{\tau}($ Region $)$ |
| $\overline{\text { STO }}$ | spatial \& temporal | $\bar{\tau}($ Point $), \bar{\tau}($ Polygon $)$ |

Note that before we can apply $\bar{\tau}$ to either geometric type $\alpha \in$ GEO we have to ensure that these are all linear smooth. Therefore, we have to identify reasonable types $\Lambda(\alpha)$. The choice here is not unique, but for points arbitrary vector movements, and for regions and polygons affine mappings provide well-understood and general models of geometric transformations that are also amenable to scalar multiplication and to the dif-
ference operator $\Delta$. Actually, scalar multiplication is already defined for both vectors and affine mappings. The $\Delta$ operation is defined for points as $\Delta(p, q)=\lambda p^{\prime} \cdot p^{\prime}+(q-p)$ where " + " and " - " are usual vector addition and subtraction. Thus, $\Delta$ simply records the vector that translates $p$ to $q$. The scalar multiplication is defined as $r \cdot\left(\lambda p^{\prime} \cdot p^{\prime}+(q-p)\right)=$ $\lambda p^{\prime} \cdot p^{\prime}+r \cdot(q-p)$, and thus the intermediate positions of a point moving from $p$ (directly) to $q$ all lie on the straight line connecting $p$ and $q$. For polygons (and regions) the difference is defined component-wise. ${ }^{4}$ For two polygons we have: $\Delta(P, Q)=\lambda p \cdot H \cdot p+v$ where the matrix

$$
H=\left(\begin{array}{ll}
a & b \\
c & d
\end{array}\right) \text { and the vector } v=\binom{v_{x}}{v_{y}}
$$

contain altogether six variables that are fully determined by three pairs of corresponding points from $P$ and $Q$ as follows. For each two corresponding points $p=(x, y)$ and $q=$ ( $x^{\prime}, y^{\prime}$ ) we know:

$$
x^{\prime}=a \cdot x+b \cdot y+v_{x} \quad \text { and } \quad y^{\prime}=c \cdot x+d \cdot y+v_{y}
$$

For three different pairs of points we thus obtain six equations which are sufficient to compute the parameters $a, b, c, d, v_{x}$, and $v_{y}$. Scalar multiplication is defined as $r \cdot(\lambda p \cdot H \cdot p+v)=\lambda p \cdot(r \cdot H) \cdot p+r \cdot v$. Now we can also see why we do not take affine mappings for points, but just vector translation: since it is not possible to infer an affine transformation from just two points, it would be impossible to define $\Delta$.

In the above table we have only listed ADTs. However, when we consider the integration into relations we can also as a further alternative distinguish the encoding of objects by a set of tuples. This applies to the spatial as well as to the temporal object part. We get the following eight modeling combinations where for each model we give its name and the attribute types ${ }^{5}$ of spatio-temporal objects (see table below).

|  | TO |  | $\overline{\mathrm{T} O}$ |  | $\mathrm{~T}(k$ snapshots) |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| SO | $\tau($ Region $)$ | STO | $\bar{\tau}($ Region $)$ | STO | Region $^{(k)}$ | SOT |
| $\overline{\text { SO }}$ | $\tau($ Polygon $)$ | $\overline{\text { STO }}$ | $\bar{\tau}($ Polygon $)$ | $\overline{\text { STO }}$ | Polygon $^{(k)}$ | $\overline{\text { SOT }}$ |
| S ( $m$ segments $)$ |  |  | $\left[\bar{\tau}(\text { Line })^{m}\right]$ | $\overline{\mathrm{T} O S}$ | Line $^{(k \cdot m)}$ | ST |

Apart from the already mentioned "full" ADT versions (i.e., spatial and temporal objects are both integrated as ADTs), the model SOT ( $\overline{\mathrm{SOT}}$ ) denotes a model where (linear) spatial objects are integrated into a tuple-timestamped temporal database: for each snapshot the currently valid version of the spatial object is stored. This is indicated by the exponent $(k)$ expressing that there are $k$ tuples representing all the $k$ snapshots. Similarly, $\bar{T} O S$ denotes the model where spatial objects (i.e., polygons) are encoded by $m$ tuples - for each segment one tuple - , and the temporal behavior is given by linear temporal objects. This means each evolving polygon is represented by $m$ temporal objects storing the behavior of each segment. This seems to be a rather unrealistic model
4. We notice that the number of components cannot change for linear areas. So we cannot model the splitting or merging of regions.
5. We give only the type for areal objects; for points all entries in the first (second) column are $\tau($ Point $)(\bar{\tau}($ Point $))$, and the third column always contains Point ${ }^{(k)}$.
(mostly because temporal object models do not exist so far), however, SOT and $\overline{\mathrm{SOT}}$ are conceivable, since spatial object models do already exist. So these two models describe the option of simply combining existing database technology for spatial and temporal databases. We have omitted a possible model TOS of unconstrained temporal objects storing segment representations of polygons, since it seems to be rather difficult to "synchronize" arbitrary temporal line objects so that they always complement into a proper polygon. Finally, the most simple model that does not use ADTs at all is the ST model which represents a changing polygon by $k \cdot m$ tuples where $m$ tuples representing one polygon snapshot get a common time stamp.

### 4.2 Expressiveness of Spatio-Temporal Models

All the different models presented above form a hierarchy which we will describe next. We obtain a representation hierarchy as shown on the right. An arrow from model $A$ to model $B$ means " $A$ is less expressive than $B$ ", i.e., $A \subset$ $B$. The edge labels serve as indices to the corresponding theorems. First, we combine and generalize results about spatial objects (see full paper) and of Theorem 3.1. Apart from
 aggregating spatial and temporal objects in an ST-REL separately (by means of $v_{S}$ and $v_{T}$ ), we can also consider the quasi-simultaneous aggregation $v_{S T}($ ST-REL $)=v_{T}\left(v_{S}(\right.$ ST-REL $\left.)\right)$. $\mu_{T^{+}}$is the extension of $\mu_{T}$ into a total function mapping to the extended representation $\mathrm{ST}^{+}-\mathrm{REL}$, and $\nu_{T^{+}}$is the corresponding extension of $v_{T}$. We also use $v_{S T^{+}}\left(\mathrm{ST}^{+}-\mathrm{REL}\right)=v_{T^{+}}\left(\mathrm{v}_{S}\left(\mathrm{ST}^{+}-\mathrm{REL}\right)\right)$. First, we can observe (see full paper):
Fact 4.1. $v_{S}($ S-REL $)=\overline{\mathrm{S} O-R E L}$ and $\mu_{S}(\overline{\mathrm{~S} O-R E L})=$ S-REL .
Now we have:
Theorem 4.2. (a) $v_{S}($ ST-REL $)=\overline{\text { SOT}} \mathbf{~} O T-$ REL
(b) $v_{S T^{+}}\left(\mu_{T^{+}}(\overline{\mathrm{T} O S}-R E L)\right)=\overline{\text { STO}}-$ REL
(c) $v_{T}($ ST-REL $) \subset \bar{T} O S-R E L$
(d) $v_{S T}($ ST-REL $) \subset \overline{\text { STO-REL }}$

Proof. Part (a) follows directly from fact 4.1. Part (b) deserves some explanations: First, we cannot simply apply $v_{S}$ to $\bar{T} O S-R E L$ because the spatial attributes are hidden in temporal objects, so we have to unpack them beforehand. However, we must be very careful here: since $\mu_{T}$ is not totally defined on $\bar{T} O S-R E L$ (ST-REL is a true subset of $\bar{T} O S-R E L$ ) we have to map to the extended representation $\mathrm{ST}^{+}$-REL by means of the extended unnesting function $\mu_{T^{+}}$. We then know: $\mu_{T^{+}}(\overline{\mathrm{T} O S}-\mathrm{REL})=\mathrm{ST}^{+}$-REL. Now we can aggregate the spatial objects and get (from part (a)): $v_{S}\left(\mathrm{ST}^{+}-\right.$REL $)=\overline{\mathrm{S}}^{+} \mathrm{T}^{+}$-REL. Finally, we can aggregate the temporal objects and obtain (as a corollary of Theorem 3.2): $v_{T^{+}}\left(\overline{\mathrm{SOT}}{ }^{+}-\mathrm{REL}\right)=\overline{\mathrm{STO}}$-REL. Part (c) follows directly from Theorem 3.1, and (d) follows from (b) and (c).
We also have corresponding results for $\mathrm{ST}^{+}$-REL:

Theorem 4.3. (a) $v_{T^{+}}\left(\mathrm{ST}^{+}-\mathrm{REL}\right)=\overline{\mathrm{T}} O S-$ REL
(b) $v_{S T^{+}}\left(\mathrm{ST}^{+}-\mathrm{REL}\right)=\overline{\mathrm{STO}}-\mathrm{REL}$

Theorems 4.2 and 4.3 express relationships of the flat relational model w.r.t. (linear) ADT models. Next we show relationships that result from the polygons being special cases of general regions.
Theorem 4.4. (a) $\bar{S} O T-R E L \subset$ SOT-REL
(b) $\overline{\text { STO}}-$ REL $\subset$ STO-REL
(c) $\overline{\mathrm{S} T O}-\mathrm{REL} \subset$ STO-REL

This theorem essentially follows from the fact that $\overline{\mathrm{S} O} \subset$ SO. Similarly, as a corollary of Lemma 3.1 we obtain the following result expressing that relations with linear temporal objects are less expressive than relations with general temporal objects:
Theorem 4.5. (a) $\overline{\text { STO}}-\mathrm{REL} \subset \overline{\mathrm{S} T O}-\mathrm{REL}$
(b) STO-REL $\subset$ STO-REL

And finally, as a corollary of Theorems 3.1 and 3.2, we obtain (note that part (a) is actually equivalent to Theorem 4.2 (c)):

Theorem 4.6. (a) $v_{T}(\overline{\mathrm{SOT}} \mathrm{OEL}) \subset \overline{\mathrm{STO}}-\mathrm{REL}$
(b) $\mathrm{v}_{T}($ SOT-REL $) \subset$ STO-REL
(c) $v_{T^{+}}\left(\overline{\mathrm{SOT}}{ }^{+}\right.$-REL $)=\overline{\mathrm{ST}} \mathrm{O}-\mathrm{REL}$
(d) $v_{T^{+}}\left(\mathrm{SOT}^{+}-\right.$REL $)=$STO-REL

It is very instructive to imagine spatio-temporal objects as 3D-objects. Then the different models presented relate directly to different features and restrictions of 3D-objects. For instance, STO describes rather arbitrary volumes (or curves in the case of points), whereas $\overline{\mathrm{S}} \mathrm{T}$ is restricted to re gion objects with polygonal f aces parallel to the $x-y$ plane. $\overline{\mathrm{STO}}(\overline{\mathrm{STO}})$ restricts STO ( $\overline{\mathrm{STO}}$ ) further to straight translations and scalings plus rotations w.r.t. the $t$-axis (for points: translations only). Two severe restrictions of STO (that result from affine mappings) are: (i) the number of components cannot change, and (ii) the number of vertices of polygons cannot change. When considering linear representations (to facilitate efficient computations) and 3D-objects, we can also imagine moving regions being represented by polyhedra. It is then interesting to note that polyhedra are not comparable in expressiveness to $\overline{\mathrm{STO}}$ : polyhedra cannot represent rotations, but they can well model changes in the numbers of components and polygon vertices.

## 5 Conclusions

We have presented a new model for temporal objects and temporal databases that, in particular, offers quite different modeling options for spatio-temporal databases. The investigation of the relative expressiveness of the different models gives a clear picture of the relationships between these models. In particular, it can be seen that, compared with the traditional (flat) view of temporal databases, the ADT approach is more versatile and offers much more control over temporal behavior, even for linearly constrained
objects. Future work should consider other specific spatio-temporal object models (such as polyhedra) in more detail.
